Assessing PVA Predictions

John D. Robinson

2026-08-31

Contents

Background

Hooker et al. (2020) used noninvasive sampling and spatial capture-recapture models to estimate the abundance of female black bears in central Georgia. Their analysis yielded point estimates of N_t between 106 and 166 using samples collected between 2012 and 2016. Using the same model, Hooker et al. (2020) also conducted population viability analyses (PVA) for the central GA black bear population. They projected abundance 50 years into the future using survival and density-dependent recruitment rates under management scenarios where a Poisson-distributed number of additional females (above current levels) were removed from the population by harvest. They evaluated *status quo* simulations (no additional harvest) and four alternatives where an average of $h = 5$, 10, 15, or 20 females (above *status quo* levels) were removed from the population by harvest. They found that 50-year extinction risk remained <1% in both the *status quo* and $h = 5$ simulations (see Figure 6 of Hooker et al. 2020).

In this markdown, we will revisit predictions from these simulations and use data for *known* female mortalities (which likely underestimates total mortality) to assess i) which scenario considered in the PVA from Hooker et al. (2020) is most similar to the recent past in central GA? and ii) which scenario do estimates of abundance from the present study (see `13_fitHooker_bothSexes`) align with most closely?
For the latter comparison, we'll use estimates from the single γ model, which estimates more realistic increases in female abundance between 2023 and 2024.

This markdown will cover the following analyses:

i. Characterize observed mortality levels in central Georgia (for comparison to alternative scenarios considered in Hooker et al. (2020))
ii. Refit the Hooker et al. (2020) model to the capture history from that study (using scripts and data from the project's GitHub repository)
iii. Repeat the PVA forecasting simulations from Hooker et al. (2020) with $h = 0$, 5, 10, 15, and 20 (as in the original paper), again using scripts from their study
iv. Compare abundance forecasts from scenarios considered in Hooker et al. (2020) to posterior distributions of female abundance from the SCR model fit in this study ("v1" model, no sex-specific recruitment)

Observed mortality in central Georgia

The Georgia Department of Natural Resources retains records of central GA black bear mortality from various sources (*e.g.*, legal harvest, illegal take, vehicular collisions, etc.). We will use those records to:

i. Visualize trends in mortality from these sources over time
ii. Calculate average numbers of deaths for three time windows
    - pre-2012: before the Hooker et al. (2020) study period
    - 2012-2016: the Hooker et al. (2020) study period, corresponding most closely to rates in their PVA
    - 2017-2024: prior to, and including, the current study period
iii. Assess predictions from the PVA in Hooker et al. (2020), given female abundance estimates from our model (`13_fitHooker_bothSexes`) and observed female mortaly data

Dataset

First load the dataset. The `.csv` file in the repository transposes data from this spreadsheet (see the `CGA Trends` tab). Below, we read the data into R, and create subsets for the two sexes and the different sources of mortality. Note that data from 2025 were not complete at the time this spreadsheet was created, so we focus on the period between 2003 and 2024.

```
mort <- read.csv("../input/CGAmortalities.csv", header = TRUE)
mort
```

```

In contrast, the vast majority of male mortality is due to vehicular collisions.

Out of curiosity, we can look for differences in mortality rates for males and females.

```
#Total

```

From the quick comparisons above, it appears that total mortality is indeed higher in males. However, legal harvest numbers are higher in females than in males. Perhaps this is due to male bears leaving the study area during the winter. The difference in harvest is more than offset by higher male mortality rates from vehicular collisions.

Average mortality numbers

To compare our abundance estimates to the predictions from simulations in Hooker et al. (2020), we first need to characterize the average total mortality for a few different periods. This way we can identify the scenario that most closely matches the data since the period covered by the Hooker et al. (2020) analysis.

Pre-2012

These numbers won't be directly used, they're included only for the sake of completeness.

```
#Combined
total.all[which(mort$year < 2012)]
```

```
## [1]  2  3 11  6  7 10 13  9 39
```

```
mean(total.all[which(mort$year < 2012)])
```

```
## [1] 11.11111
```

```r
median(total.all[which(mort$year < 2012)])
```

```
## [1] 9
```

```r
#Females
total.female[which(mort$year < 2012)]
```

```
##  1  2  3  4  5  6  7  8  9
##  2  2  3  1  1  1  4  5 18
```

```r

## [1] -1
```

In fact, mean and median female mortality numbers since 2017 are lower than they were during the Hooker et al. (2020) study period. The *maximum* single year total mortality of females since the Hooker et al. (2020) study is **3.4 bears** above the mean for their study period. Notably, annual female mortality since 2017 has exceeded the average from the Hooker et al. (2020) study period in 4 years (the last years considered, 2021-2024).

```r
plot(total.female[which(mort$year < 2025)] ~ mort$year[which(mort$year < 2025)],
     type = "b", lwd = 1, col="black", pch=19,
     xlab = "Year", ylab = "Total Mortality", main = "Females")
abline(h = mean(total.female[which(mort$year %in% c(2012:2016))]),
       lty = 3, col="red", lwd = 2)
legend("topleft", bty="n", cex = 0.75,
       lty=c(1,3), pch=c(19,19), pt.cex=c(1,0), lwd = c(1,2),
       col = c("black","red"),
       legend = c("Observed","Mean: 2012-2016"))
polygon(x=c(2011.75,2011.75,2016.25,2016.25),y=c(-100,100,100,-100),
        col=alpha("grey",0.2), lty=2, lwd = 0.5)

  mean(total.female[which(mort$year %in% c(2012:2016))])
```

```
##  19  20  21  22
## 2.4 3.4 2.4 1.4
```

In terms of the two major sources of mortality, average legal harvests since 2017 are down by 2.125 females, while average vehicular collisions are up by 1 females.

Assess PVA predictions

Given the female mortality observed since the Hooker et al. (2020) study period, and the lower mean annual harvest numbers, management of the central GA black bear harvest has been effective at limiting annual female mortality.

The average total *known* female mortality since the Hooker et al. (2020) study (7.375) was below the average total mortality from the Hooker et al. (2020) study period (7.6), while the maximum single-year mortality since 2016 (11 females in 2022) was slightly higher. Thus, observed total *known* female mortality in central GA is most consistent with the two lowest harvest rate scenarios from Hooker et al. (2020), *status quo* or $h = 5$ expected additional females harvested per year.

Under both of these scenarios, 50-year extinction risks in the PVA remained below 1%, and population size was relatively stable (Hooker et al. 2020). Quoting from their Discussion section:

From an abundance of 165 (95% CI = 134–206) in 2016, the 50-year population forecasts (i.e., estimated abundance in the year 2067) for each of the 5 harvest scenarios in order of lowest to highest harvest were 169 (95% CI = 134–268), 159 (95% CI = 124–243), 147 (95% CI = 103–223), 132 (95% CI = 0–197), and 105 (95% CI = 0–174). Extinction probabilities for the status quo scenario (i.e., the lowest level of harvest of any of the scenarios) was negligible at <0.001% with no abundance projections falling to zero during the 50-year timeline. Similarly, the scenario in which the status quo harvest was increased by 5 females had few projections in which abundance dropped to zero, resulting in an extinction risk of <1%. –Hooker et al. (2020)

Re-fit the Hooker model

To quantify the degree to which our estimates of female abundance align with predictions from the population viability analyses of Hooker et al. (2020), we will first re-fit the model to capture data for female bears. The files needed to do this are available on the Hooker et al. (2020) GitHub repository: `dT-s0-rPDD2-phi0-pYB-sig0.jag`, `fit.R`, `ga_bear_data_females.gzip`, and `state-space360.tif`.

```
#Code below is copied from fit.R
# paths to the JAGS model, capture history data, and state space file
# are modified slightly

Compare forecasted abundance

Now we'll look at the distribution of projected population sizes under each of the management alternatives (*status quo*, +5, +10, +15, or +20 additional females harvested) and ask where our median parameter estimates for female abundance in 2023 and 2024 fall in those distributions.

```r
load("forc-h0.gzip")
load("forc-h5.gzip")
load("forc-h10.gzip")
load("forc-h15.gzip")
load("forc-h20.gzip")

#Calculate median population size for each draw from the posterior
# 2000 total draws, each simulated 100 times over a period of 50 years
dim(forc.h0$Nbar)
```

fyrs <- 2017:(2017+50)
# ---
```

Visual comparisons

Now plot the full time series with our abundance estimates included. We focus on the v1 model, with a single recruitment rate parameter shared by males and females, as the estimates of γ are more reliastic under this model.

```r
library(scales)

Quantifying "fit" of the scenarios

Can we distinguish between the "fit" of the scenarios simulated in Hooker et al. (2020) to our abundance estimates from 2023 and 2024? There is substantial overlap in the predictions from the model with more limited harvest rates, partially due to the assumption of Poisson-distributed annual harvest (*i.e.*, with $h = 5$, we are not removing exactly 5 bears from the population each year). Notably, annual known mortality numbers since the Hooker et al. (2020) study were most similar to the *status quo* or 5 additional females removed scenarios (see above). However, we are still interested in assessing whether the different scenarios generate distinguishable predictions for abundance.

To assess the fit of our estimates (*i.e.*, posterior distributions of female abundance in 2023 and 2024) to the management scenarios from Hooker et al. (2020), we will calculate Kullback-Leibler divergence (D_{kl})

between the distributions of simulated abundance under each scenario and the posterior distribution of estimated abundance for each of the two study years. We'll use the `kld_est_nn()` function from the `kldest` R package (Hartung 2024) to estimate KL divergence between our forecasts and posteriors with a nearest-neighbor approach.

```r
#First collect the distributions of abundance from the forecasts
# combine these into one data frame from each of the scenarios
# these will be the distributions that we compare to posteriors
h0df <- data.frame(n23 = EN21.h0[which(fyrs == 2023),],
                   n24 = EN21.h0[which(fyrs == 2024),])
h5df <- data.frame(n23 = EN21.h5[which(fyrs == 2023),],
                   n24 = EN21.h5[which(fyrs == 2024),])
h10df <- data.frame(n23 = EN21.h10[which(fyrs == 2023),],
                   n24 = EN21.h10[which(fyrs == 2024),])
h15df <- data.frame(n23 = EN21.h15[which(fyrs == 2023),],
                   n24 = EN21.h15[which(fyrs == 2024),])
h20df <- data.frame(n23 = EN21.h20[which(fyrs == 2023),],
                   n24 = EN21.h20[which(fyrs == 2024),])

#Now combine posteriors in the same fashion
# this is the "true" distribution we're seeking to approximate
load("../scr/samples-bothSexes_v1.gzip")
out <- coda::as.mcmc.list(samples)

est.df <- data.frame(n23 = unlist(out[,"Nf[1]"]),
                     n24 = unlist(out[,"Nf[2]"]))

#Now calculate divergence for each scenario, using 50 nearest neighbors...
library(kldest)

kld_est_nn(X=est.df, Y=h0df, k=50) #status quo
```

```
